Latex is an important application for dynamic light scattering. In addition, monodisperse latex standards are often used to evaluate instrument performance. Frequently these materials are polystyrene and called “PSL standards” where PSL stands for polystyrene latex. Typically, these standards are sold at relatively high concentration (0.1%) and must be diluted in order to test instrument performance. Often, issues with the results are due to issues with the sample. This note discusses sample preparation.

Introduction

Dynamic light scattering (DLS) is the technique of choice for analyzing the size of submicron particles including nanoparticles (1). DLS can be used to characterize particles with sizes ranging from less than a nanometer to several microns. The measurement is fast and repeatable and the volume of liquid required can be as little as 10 microliters. In addition, particle charge, that is, zeta potential can be determined with an appropriately enhanced DLS instrument.

Nanoparticle size distribution analyzers such as the SZ-100 need to be evaluated with check standards in order to ensure that they are performing properly. Due to the nature of the instrument, if the wrong answer is obtained then the instrument will require repair. That is, there are no “adjustments” to the results. Fortunately, in the vast majority of cases, the issue is the sample preparation, not the instrument.

Method

First prepare a 10 mM solution of NaCl or KCl or any other 1:1 electrolyte. Use de-ionized laboratory water to avoid any “surprise” effects such as from polyvalent ions (e.g., Ca++).

Below is a table of the mass of NaCl (58.44 g/mol) or KCl (74.55 g/mol) required when preparing the solution.

<table>
<thead>
<tr>
<th>Volume solution (DI water)</th>
<th>grams NaCl</th>
<th>grams KCl</th>
</tr>
</thead>
<tbody>
<tr>
<td>100 mL</td>
<td>0.0584</td>
<td>0.0745</td>
</tr>
<tr>
<td>1000 mL</td>
<td>0.584</td>
<td>0.745</td>
</tr>
</tbody>
</table>

Next the solution must be filtered to remove any dust. Load 10 mL of the salt solution into a 10 mL or larger syringe. Add a 0.2 nm or smaller pore size filter and slowly push the liquid through the filter into a 20 mL scintillation vial or similar vessel. For the case of ~100 nm PSL, use about 10 mL of liquid.
Inspect the tip of the bottle of standard to ensure that it is clean. Then, put one drop of standard into a waste container. This is an additional cleaning step. For the case of ~100 nm PSL, add one drop to the 10 mL of liquid. This will give a concentration of about 30 ppm (w/w). Note that the concentration is quite approximate. A final concentration of 15 to 60 ppm is fine.

Inspect the material for any visible dust particles. There should be none. If there are any, discard and start again.

Pour the liquid into a clean cuvette and measure for one minute.

If the initial results are poor, try making the sample again from scratch.

Conclusions

By careful attention to suspension preparation, reliable information about DLS instrument condition can be obtained.
